Increase strength and mood

with posture

Erik Peper, PhD, BCB*, Annette Boorman, MSCT, BCB*, I-Mei Lin, PhD, BCB*, & Richard Harvey, PhD*

We thank Dr. Donald Moss for editing and improving the manuscript.

Body posture can project non-verbally how we feel (Coulson, 2004; Pitterman & Nowicki, 2004). For example, when standing erect we occupy more space and tend to project power and authority to others and to ourselves (Huang, Galinsky, Gruenfeld, & Guillory, 2010). When we feel happy, we walk erect with a bounce in our step. We may jump with joy when we achieve our goals or collapse when we receive bad news. More and more in contemporary life we sit collapsed for many hours with our spine in flexion. We crane our heads forward to read text messages, a tablet, a computer screen, or to watch TV (Straker et al, 2008; Asunda, Odell, Luce, & Dennerlein, 2010). Our bodies collapse when we think hopeless, helpless, powerless thoughts, or when we are exhausted. We tend to slouch and feel “down” when depressed (Canales, Cordás, Fiquer, Cavalcante, & Moreno, 2010).

We may shrink and collapse our posture to protect ourselves from danger when we feel threatened because in prehistoric times this reaction would protect us from predators as we were still prey (Ogden, Minton, & Pain, 2006). In modern times we may still give the same reaction when we worry or respond to demands from our boss (Andrews, Wadwaalla, Juster, Lord, Lupien, & Pruessner, 2007). Under cognitive (social evaluative) threat compared to the threat of being physically harmed we may blank out and have difficulty thinking and planning for future events (Fraizer & Mitra, 2007). When the body reacts defensively, the whole body-mind focuses on immediate survival. Rational and abstract thinking is reduced as we attempt to escape (Ernst-Vintila, Delouvee, & Roland-Levy, 2011).

Emotions and thoughts affect our posture and energy levels; conversely, posture and energy affect our emotions and thoughts (Peper & Lin, 2012). For example, Peper and Lin (2012) have shown that when we are skipping our energy increases significantly versus walking in a slouching posture for two minutes, which diminishes energy levels. Furthermore, if you have reported feeling chronically depressed over the last two years, you experience a significant drop in subjective energy when walking in a slouching posture for two minutes. Posture also affects recall of positive or negative memories; Wilson and Peper (2004) observed that if you sit in a collapsed position, it is easier to recall hopeless, helpless and powerless memories compared to positive empowering memories. In contrast, when participants sat in an erect, upright posture it was easier to recall positive empowering memories compared to hopeless, helpless and powerless memories.

“I couldn’t believe it, I could not think of any positive thoughts while looking down!”

Figure 1. Experimenter pressing down on the arm while the subject resists the downward pressure
These findings were confirmed in an elegant study on positive and negative words recall while participants walked on a treadmill in two different postures for which they received feedback (Michalak, Rohde, & Troje, 2014). In a slouched (depressed) posture, participants recalled significantly more negative words than when they walked in an upright, erect body posture as if they were happy.

Hormone levels also change in a collapsed posture (Carney, Cuddy, & Yap, 2010). For example, two minutes of standing in a collapsed position significantly decreased testosterone and increased cortisol as compared to a ‘power posture,’ which significant increased testosterone and decreased cortisol while standing. As Cuddy pointed out in a Technology, Entertainment and Design (TED) talk, “By changing posture, you not only present yourself differently to the world around you, you actually change your hormones” (Cuddy, 2012). As Boorman and Peper (2010) reported, when an individual presents a more erect posture to the world, the world around him or her may respond in a more positive way. For example, when a shy and slouched person attempts to sit beside you at a party, the first thought of many people is, “Oh no, not the whole evening.” While if that person had an open and more erect posture and asked to join your table, your first thought and response could be, “Yes of course, please sit down.” These subtle thoughts and non-verbal communications affect people’s social experiences (Boorman & Peper, 2010).

Subtle changes in posture affect our psychophysiology, which is a phenomena well known in sports as “psyching out” (Vealey, 2009). When people are intimidated or somehow know they cannot win, they often give up and slightly collapse. When people are taught awareness and change of posture in randomized controlled trials with the educational Alexander technique, the therapeutic Mensendieck Method, or other somatic approaches, numerous dysfunctions can be improved such as back and balance (Little et al., 2008; Dennis, 1999; Jones, 1976; Haugstad et al., 2006; Haugstad et al., 2008). The objectives of this study were: 1) to explore how changes in body posture while standing affect strength, as perceived by both the experimenter and subject, and 2) to apply this somatic feedback experience to encourage awareness and facilitate changes in beliefs.

**“Don’t slouch! How many times do I have to tell you to sit up straight?”**

**Methods**

Participants: 33 physical therapists (5 males, 25 females, 3 not specified), average age 46.2 (SD = 12.4).

Procedure: In this study, all participants paired up as ‘testers’ or ‘subjects’ and took turns testing each other while standing either in an erect or collapsed/sloshed posture. Each pair proceeded through a manual muscle testing (MMT) procedure (Mendell, & Florence, 1990; Schmitt, & Cuthbert, 2008) by raising each arm and attempting to resist the steady downward pressure applied by the tester to a forearm near the wrists. The testers determined which outstretched arm was stronger, then all of the testing proceeded with the strongest arm. The subjects stood either in an erect posture or collapsed posture while they raised their arm and attempted to resist the downward pressure applied to their forearm near the wrists. The order of collapsed or erect posture was counterbalanced. The specific instructions were:

Stand behind your partner and ask her/him to lift her/his right arm straight out as shown in Figure 1. For each test, apply the same gentle pressure downward on the right (or dominant) forearm near the wrist while your partner attempts to resist the downward pressure. Apply enough pressure downward so that the right arm begins to go down. Then relax and repeat the same manual muscle test exercise with the left (or non-dominant) arm. Then relax. Thereafter use the arm that felt the strongest and resisted the downward pressure the most.

Continue with the following sequence. Half the subjects started with the slouched position, followed by the erect/tall position and the other half started with the erect position followed by the slouched position. The testers stood behind their partners so there was no overt visible feedback of what could be observed from the face of the subjects by the testers. The subjects lifted their strongest arm straight out and the tester applied a gentle pressure downward at the forearm so that the arm began to go down while the subject attempted to resist the downward pressure. After this manual muscle test procedure, the subjects were asked to relax and let their arm hang beside their body.

The subject then stood in the second position (either slouched or erect/tall) and again lifted the same arm straight out. The tester applied the same manual muscle test pressure downward so that arm began to go down while the subjects attempted to resist the downward pressure. Again, after the test, the subjects were asked to relax and let their arm hang beside their body. Both subjects and testers recorded their subjective experience, rating the effort they perceived on the scale from -3 (weaker) to 0 (no change) to +3 (stronger), while resisting the downward pressure of the arm down. These perceptions of strength were rated while standing erect as well as in a slouched posture.

**Results**

An Analysis of Variance (ANOVA) showed that subjects subjectively felt stronger and were more able to resist the downward pressure when they stood in an erect/tall posture as compared to a collapsed posture F(1, 58) = 85.9, p < .001). 98% of the subjects felt that their arm was stronger when standing erect. ANOVA also showed the “testers” felt that the subjects were much stronger in their ability to resist the downward pressure in the erect/tall versus collapsed position F(1, 59) = 74.6, p < .001), as shown in Figure 2. The subjective rating of the subjects and the testers pressing down on the arm were not significantly different as measured with t-test (erec p = 0.46; collapse p = 0.50).

![Figure 2. The perceived strength to resist the down pressure on the arm in either the erect or collapsed position as observed by the subjects and the testers.](image-url)
There was a negative correlation between perceived strength and severity of reported depression (r = -.4).

Discussion

The subjective experience of strength is a metaphor of how posture affects our thoughts, emotions, hormones and immune system. When slouching, the subjects experienced less strength to resist the downward pressure and feels weaker. In this state it is much more challenging to project authority, to think creatively, and to solve problem successfully. Obviously, the loss of strength relates to the change in the shoulder/body biomechanics and affects muscle activation recorded from the trapezius, medial and anterior deltoid when the person resists the downward applied pressure. The SEMG of the upper trapezius, medical and anterior deltoid muscles is significantly higher when erect as compared to slouched position (Peper et al, 2015).

In the slouched position, the subjects felt more hopeless, helpless, and powerless. Memories are embedded and conditioned with our body posture and body postures covertly evokes the associated memories, thoughts, and emotions as well as shifts our energy level.

In a therapeutic/educational setting with sceptical clients, this exercise can be repeated numerous times and the outcome will be the same, no matter which arm, which order of position or how often it is repeated. The clients can use the change in body posture (e.g. collapsed to erect posture) to learn to identify internal and external cues that trigger the change in posture, and substitute alternative behavior (Peper, Lin, et al., in press). For example, students at San Francisco State University have often reported that they blank out on exams or class presentations while in a collapsed posture. When they become aware of their collapsed posture, and then shift to standing erect, in an assertive power posture while breathing slowly and diaphragmatically, they report feeling calmer and can think again. Similarly, clients who are experiencing worry, sadness, and discomfort may be able to shift their posture and look upward with their eyes. In this new posture they often find it is easier to think of positive options.

The power of posture on memory recall can also be experienced in the following exercise (Wilson & Peper, 2004; Gorter & Peper, 2011).

Posture Affects Memory Recall

Sit comfortably on a chair and then collapse downward so that your back is rounded like the letter C. Let your head tilt forward and

You can lighten your mood and give yourself the opportunity to be empowered and hopeful when you shift your posture.
The clients can use the change in body posture to learn to identify internal and external cues that trigger the change in posture, and substitute alternative behavior

After having done these two practices, I realized how powerful my body effects my mood and energy level. Now each time I am aware that I collapse, I change my posture while breathing exhaling, and often stand up and stretch. To my surprise, I have so much more energy and my negative depressive mood has lifted.

I never realized that changing my posture in a more straight position makes my exercises so much easier. Now I can repeat them many more times with less effort.

--21 year old male student

look at the floor between your thighs as shown in Figure 3.

While in this position, recall hopeless, helpless, powerless, and depressive memories one after the other for thirty seconds.

Then, let go of those thoughts and images, and, without changing your position and still looking downward, recall empowering, positive, and happy memories one after the other for thirty seconds.

Shift position and sit up erect, with your spine slightly arched with a functional curve and your head held tall while looking slightly upward as shown in Figure 4.

While sitting in this position, recall as many hopeless, helpless, powerless, or depressive memories one after the other for thirty seconds.

Then, let go of those thoughts and images. Without changing position and while still looking upward, recall as many empowering, positive, and happy memories one after the other for thirty seconds.

Ask yourself: In which position was it easier to evoke negative memories and in which position was it easier to evoke empowering, positive, and happy memories?

Overwhelmingly participants report that in the downward position it was easier to recall negative and hopeless memories. By contrast in the upright positon they report it was easier to recall positive and empowering memories. In many cases, participants reported that when they looked down, they could not evoke any positive and empowering memories. It is not surprising that when people feel optimistic about the future, they say, “Things are looking up.” Mind and body affect each other. The increase in depression and fatigue may be in part be caused by sitting or standing in a collapsed posture at work, at home and/or walking in a slouched pattern. When an individual shifts from a collapsed, slouching body posture to an erect posture or switches from walking in a slouching position to skipping with one’s head held high, a sense of subjective energy may significantly increase (Peper & Lin, 2012; Peper, 2012).

You can lighten your mood and give yourself the opportunity to be empowered and hopeful when you shift your posture. When feeling down, it is okay to acknowledge the feeling and say, “At this moment, I am feeling overwhelmed, and I’m not sure what to do.” When your energy is low, again acknowledge this to yourself: “At this moment I feel exhausted,” or “At this moment, I feel tired,” or whatever phrase fits the feeling. As you acknowledge it, be sure to state “at this moment.” The phrase “at this moment” is correct and accurate. It implies what is occurring without a self-suggestion that the feeling will continue, which helps to avoid the idea that this was, is, and will always be. The reality is that whatever we are experiencing is always limited to this moment, as no one knows what will occur in the future. This leaves the future open to change and new possibilities.

Remind yourself that you can shift your mood by changing your posture as well as with movement (Martinsen, 2008; Carek, Labstain, & Carek, 2011). For example, when you are outside, focus on the clouds moving across the sky, the flight of birds, or leaves on the trees. In your home, you can focus on some inspiring art on the wall, or photos of family members you love and who love you. To increase access to positive feelings, hang the positive pictures slightly higher on the wall so that you have to look up. You can also put pictures above your desk or as a screen saver on your laptop or smartphone to remind and to evoke positive memories. In addition, when using your car, adjust the inside rear view mirror so that you sit more erect to see. Observe that at the end of the day you tend to readjust the mirror when you are tired. Instead of adjusting the mirror, adjust your posture by arching your back slightly while breathing out and stretch your neck to look upward with a smile. Or, before driving away, walk a little bit farther by putting your car at the end of the parking lot instead of as close as possible to the front door.

**Conclusion**

An essential part of the holistic approach to health and wellness involves incorporating awareness of body posture, movement and providing some form of somatic feedback as part of the therapeutic and patient education process. Without teaching that a collapsed body posture may impact the healing process, only one half of the mind-body equation that underlies health and illness will be impacted. The body affects the mind/emotions just as the mind/emotions affect the body; shifting posture will shift mood. The somatic feedback approach is another strategy for clients for whom cognitive therapy approaches are challenging. Using the concepts derived from these studies, apply them to yourself and clients.

Each time you collapse or have negative thoughts, change your position to a more erect position. It only takes two minutes of posture change to initiate changes in your hormones, energy levels, strength and moods. These two minute changes done often may change your life. Think about—and change—your posture while standing in line, sitting at the computer waiting for the microwave to heat the food, or the printer warm up, etc. Finally, instruct yourself to get up and move about frequently to prevent low energy and depression. Stretch and walk around, stand straight and feel the weight on both feet while you imagine you are like a tree—rooted in the earth while reaching upward to the light.
